# Relaxed Gradient Descent and a New Gradient Descent Methods for Unconstrained Optimization 

Neculai Andrei ${ }^{1}$

#### Abstract

In this work we present two techniques for steplength selection in the frame of gradient descent methods. Using a simple multiplicative modification of the steplength, given by a backtracking procedure, by means of a random variable uniformly distributed in $(0,1]$ we get the relaxed gradient descent method. The second algorithm selects the steplength along the negative gradient using a new approximation of the Hessian of the minimizing function based on the function values and its gradients in two successive points along the iterations. Both algorithms belong to the same class of gradient descent with linear convergence property.

Some preliminary numerical experience shows that the second algorithm compares favourable with the Barzilai-Borwein approach. The main advantage of this new algorithm is the possibility to continue the iterations when the approximation of the Hessian is unproperly chosen.

Keywords: gradient descent methods, relaxed gradient descent, Barzilai-Borwein method

## 1. Introduction

One of the first and well known method for unconstrained optimization is the gradient descent method, designed by Cauchy early in 1847, in which the negative gradient direction is used to find local minimizers of a differentiable function. The method proved to be effective for functions very well conditioned, but for functions poorly conditioned the method is excessively slow, thus being of no practical value. Even for quadratic functions the gradient descent method with exact line search behave increasingly badly when the conditioning number of the matrix deteriorates. Early attempts to increase the performance of the method have been considered by Humphrey [19], Forsythe and Motzkin [11] and Schinzinger [31]. Even though the storage requirements for the gradient descent method are minimal ( $3 n$ locations for a n-dimensional problem), the development of conjugate gradient and quasi-Newton methods for large-scale unconstrained optimization cast the gradient descent method in a penumbra.

In 1988 Barzilai and Borwein [2] proposed a gradient descent method (BB method) that uses a different strategy for choosing the step length. This is based on an interpretation of the quasi-Newton methods in a very simple manner. The steplength along the negative gradient direction is computed from a two-point approximation to the secant equation from quasi-Newton methods. In [2] Barzilai and Borwein proved that for the two-dimensional

[^0]quadratic case the BB method is R -superlinear convergent. They present some numerical evidence showing that their method is remarkably superior to the classical gradient descent method for a quadratic function with four variables.

Raydan [28] proved that for strictly convex quadratic case with any number of variables the BB method is globally convergent. Using a globalization strategy, based on the non-monotone line search technique introduced by Grippo, Lampariello and Lucidi [17], Raydan [29] proved the global convergence of the BB method for non-quadratic functions and reports some numerical evidence on problems up to $10^{4}$ variables showing that the BB method is competitive with the conjugate gradient Polak-Ribière [25] and CONMIN of Shanno and Phua [32] methods. A preconditioning technique for the BB method has been considered by Molina and Raydan [21]. Under a very restrictive assumption they established the Q-linear rate of convergence of the preconditioned BB method. Some applications of preconditioned BB method on a distance matrix problem are considered by Glunt, Hayden and Raydan [14, 15]. Extension of the BB method for box-constrained optimization problems have been considered by Friedlander, Martinez and Raydan [13] (for quadratic function) and by Birgin, Martinez and Raydan [3].

An analysis of the BB method stressing the importance of non-monotone line search as well as some open problems are presented by Fletcher [9]. Dai and Liao [5] refined the analysis in Raydan [28] and proved that the convergence rate is R-linear. New globalization strategies for BB method, based on relaxations of the monotonicity requirements, are considered by Grippo and Sciandrone [18] where the nonmonotone watchdog technique with nonmonotone linesearch rules are combined. Their algorithms are very sophisticated and dependent of a number of parameters. Numerical experience and comparisons with E04DGF routine of NAG library on some collections of problems, including CUTE, shows that their globalization strategy for the BB algorithm compares favorables with E04DGF algorithm. (However, for some difficult ill-conditioned problems, algorithm E04DGF is more efficient.)

Recently, for the quadratic positive definite case Raydan and Svaiter [30] consider the relaxed gradient method as well as the Cauchy-Barzilai-Borwein methods showing the superiority of the last one against the relaxed gradient descent and BB methods, Particularly, the Cauchy-Barzilai-Borwein method proves to be Q-linearly convergent in a norm defined by the matrix of the problem.

The purpose of this paper is twofold. The first one is to extend the relaxed gradient method to the convex, well conditioned, functions. It is shown that for strongly convex, well conditioned minimization problems the relaxed gradient descent algorithm is an improvement of the classical gradient descent version. The second purpose of the paper is to present a new algorithm of gradient descent type, in which the step size is computed by means of a simple approximation of the Hessian of the minimizing function. In contrast with the Barzilai and Borwein approach in which the steplength is computed from a simple interpretation of the secant equation, the new proposed algorithm considers another approximation of the Hessian based on the function values and its gradients in two successive points along the iterations. The corresponding algorithm belongs to the same class of linear convergent descent methods. The conclusion is that using only the local information given by the gradient, any procedure for step size computation, of any sophistication, does
not change the linear convergence class of algorithms.
The paper is organized as follows. Section 2 is dedicated to present the relaxed gradient descent algorithm and its properties. In section 3 we present a new algorithm for unconstrained optimization in which the steplength is computed by backtracking starting with the inverse of a scalar approximation of the Hessian. Section 4 contains some numerical evidence and discussions of this approach.

## 2. The Relaxed Gradient Descent Method

In the following let us consider the problem:

$$
\begin{equation*}
\min f(x) \tag{1}
\end{equation*}
$$

where $f: R^{n} \longrightarrow R$ is convex and twice continuously differentiable. A necessary and sufficient condition for a point $x^{*}$ to be optimal for (1) is

$$
\begin{equation*}
\nabla f\left(x^{*}\right)=0 . \tag{2}
\end{equation*}
$$

Usually, the problem is solved by an iterative algorithm which generates a sequence of points $x_{0}, x_{1}, \ldots \in \operatorname{dom} f$, for which $f\left(x_{k}\right) \longrightarrow f^{*}$ as $k \longrightarrow \infty$. The algorithms for solving (1) generate a minimizing sequence $x_{k}, k=0,1, \ldots$ as:

$$
\begin{equation*}
x_{k+1}=x_{k}+t_{k} d_{k} \tag{3}
\end{equation*}
$$

where the scalar $t_{k}>0$ is the step size, and the vector $d_{k}$ is the search direction.
Many procedures for search direction computation have been proposed. One of the first method, and the simplest one, for solving (1) using (3) was the gradient descent method (Cauchy method [4]) where the choice for the search direction at the iteration $x_{k}$ is the negative gradient, $-\nabla f\left(x_{k}\right)$. Some other known methods dedicated for large-scale problems are based on the conjugate gradient strategy. The simplest methods are those of Fletcher and Reeves [10] (using $3 n$ locations) and of Polak and Ribière [25] (using $4 n$ locations). More elaborate methods that use more storage are those of Shanno and Phua [32] (CONMIN that use $7 n$ locations), the Limited Memory BFGS method of Nocedal [24] (using more than $9 n$ locations), the Truncated Newton method of Dembo, Eisenstat and Steihaug [6] (an excellent survey of truncated-Newton methods has been given by Nash [23]), etc.

On the other hand, for step size selection two main algorithms have been considered: exact line search and backtracking line search. In exact line search the step $t_{k}$ is selected as:

$$
\begin{equation*}
t_{k}=\underset{t>0}{\arg \min } f\left(x_{k}+t d_{k}\right) \tag{4}
\end{equation*}
$$

In some special cases (for example quadratic problems) it is possible to compute the step $t_{k}$ analytically, but in most cases it is computed to approximately minimize $f$ along the ray $\left\{x_{k}+t d_{k}: t \geq 0\right\}$, or at least to reduce $f$ enough. In practice the most used are the
inexact procedures which try to reduce $f$ enough. Many inexact line search methods have been proposed: Goldstein [16], Armijo [1], Wolfe [33], Powell [27], Denis and Schnabel [7], Fletcher [8], Potra and Shi [26], Lemaréchal [20], Moré and Thuente [22], and many others.

One which is very simple and efficient is the backtracking line search. This procedure considers two constants $0<\alpha<0.5$ and $0<s<1$ and takes the following steps:

Step 1. Consider the descent direction $d_{k}$ for $f$ in point $x_{k}$. Set $t=1$.
Step 2. While $f\left(x_{k}+t d_{k}\right)>f\left(x_{k}\right)+\alpha t \nabla f\left(x_{k}\right)^{T} d_{k}$, set $t=t s$.
Step 3. Set $t_{k}=t$.
Typically, $\alpha=0.0001$ and $s=0.8$, meaning that we accept a small decrease in $f$ of the prediction based on the linear extrapolation.

One goal of this paper is to show that the linear behavior of the gradient descent method for well-conditioned functions could be improved by a subrelaxation of the step size. For quadratic positive definite problems an overrelaxation have been considered by Raydan and Svaiter [30]. They proved that the poor behavior of the steepest descent methods is due to the optimal Cauchy choice of step size and not to the choice of the search direction. In this paper we extend these results to convex, well conditioned functions. The idea is to modify the gradient descent method by introducing a relaxation of the following form:

$$
\begin{equation*}
x_{k+1}=x_{k}+\theta_{k} t_{k} d_{k} \tag{5}
\end{equation*}
$$

where $\theta_{k}$ is the relaxation parameter, a random variable uniformly distributed between 0 and 1. With this, the Relaxed Gradient Descent algorithm can be presented as:

## Relaxed Gradient Descent Algorithm (RGD)

Step 1. Consider a starting point $x_{0} \in \operatorname{domf}$. Set $k=0$.
Step 2. Compute the search direction: $d_{k}=-\nabla f\left(x_{k}\right)$.
Step 3. Line search. Choose the step length $t_{k}$ via exact or backtracking line search procedures.

Step 4. Update the variables: Select $\theta_{k} \in(0,1)$ and update the variables: $x_{k+1}=$ $x_{k}+\theta_{k} t_{k} d_{k}$.

Step 5. Test a criterion for stopping the iterations. If the test is satisfied, then stop; otherwise consider $k=k+1$ and continue with step 2.

Clearly, if $\theta_{k}=1$ for all $k$ we get the classical Gradient Descent (GD) method.
Example 1. Let us illustrate the behavior of the relaxed gradient descent method in comparison with the classical gradient descent on the following function:

$$
f(x)=\sum_{i=1}^{n} i x_{i}^{2}+\frac{1}{100}\left(\sum_{i=1}^{n} x_{i}\right)^{2} .
$$

Considering $x_{0}=[0.5,0.5, \ldots, 0.5], \alpha=0.0001$ and $s=0.8$ in backtracking procedure, as well as the following criteria for stopping the iterations

$$
\left\|\nabla f\left(x_{k}\right)\right\| \leq \varepsilon_{g} \quad \text { or } \quad \frac{\left|f\left(x_{k+1}\right)-f\left(x_{k}\right)\right|}{1+\left|f\left(x_{k}\right)\right|} \leq \varepsilon_{f}
$$

with

$$
\varepsilon_{g}=10^{-6} \text { and } \varepsilon_{f}=10^{-16}
$$

than for $n=100$, the evolution of the norm $\left|f\left(x_{k}\right)-f^{*}\right|$ given by the gradient descent method and of the relaxed gradient descent method are presented in figure 1.

Figure 1: Gradient Descent versus Relaxed Gradient Descent

Table 1a shows the number of iterations corresponding to these algorithms, as well as the average steplength, for different values of $n$, using the above criteria for stopping.

Table 1a. Number of iterations and the average steplength.

|  | GD |  | RGD |  |
| :---: | :---: | :---: | :---: | :---: |
| $\mathbf{n}$ | \# iter | average step | \# iter | average step |
| 500 | 3105 | 0.002006 | 463 | 0.0209455 |
| 1000 | 6129 | 0.0010003 | 505 | 0.0144660 |
| 2000 | 12147 | 0.0005011 | 1256 | 0.0088871 |
| 3000 | 16773 | 0.0003349 | 1146 | 0.0097431 |
| 4000 | 22722 | 0.0002516 | 1177 | 0.0061838 |
| 5000 | 27910 | 0.0002013 | 1523 | 0.0071524 |

Observe that the relaxed version of gradient descent method clearly outperforms the classical gradient method. Both methods exhibits a linear convergence to the minimizer of
the function, but RGD algorithm takes a significant smaller number of iterations. Similar results have been obtained using different random number generators in interval $(0,1)$. The parameters $\alpha$ and $s$ from backtracking linear search has a noticeable but not a dramatic influence on the number of iteration. Numerical experiments with different values for $\alpha$ leads to the same behaviour of the algorithm. Observe that the average stepsize in RGD algorithm is greater as in GD version. This explains its efficiency.

This numerical experiment reveals the serious limitation of the steplength choice by backtracking when searching is along the negative gradient. This reveals a lack of robustnees of the gradient descent algorithm with backtracking at steplength perturbations.

The convergence analysis of RGD algorithm is given by the following theorems.
Theorem 1. If the sequence $\theta_{k}$ has an accumulation point $\bar{\theta} \in(0,1)$, then, for strongly convex functions, the sequence $x_{k}$ generated by RGD algorithm converges linearly to $x^{*}$.

Proof. Let us consider: $\Phi_{k}(\theta)=f\left(x_{k}-\theta t_{k} g_{k}\right)$, where $g_{k}=\nabla f\left(x_{k}\right)$. We can write:

$$
f\left(x_{k}-\theta t_{k} g_{k}\right)=f\left(x_{k}\right)-\theta t_{k} g_{k}^{T} g_{k}+\frac{1}{2} \theta^{2} t_{k}^{2} g_{k}^{T} \nabla^{2} f\left(x_{k}\right) g_{k}
$$

Since the function $f$ is strongly convex it follows that $\Phi_{k}(\theta)$ is a convex function and $\Phi_{k}(0)=f\left(x_{k}\right)$. From the strong convexity of $f$ it follows that:

$$
\begin{equation*}
f\left(x_{k}-\theta t_{k} g_{k}\right) \leq f\left(x_{k}\right)-\left(\theta-\frac{M t_{k}}{2} \theta^{2}\right) t_{k}\left\|g_{k}\right\|_{2}^{2} \tag{6}
\end{equation*}
$$

But $\theta-\frac{M t_{k}}{2} \theta^{2}$ is a convex and nonnegative function on $\left(0,2 / M t_{k}\right)$ and has the maximum value equal with $1 / 2 M t_{k}$ in $1 / M t_{k}$. Therefore $f\left(x_{k+1}\right) \leq f\left(x_{k}\right)$ for all $k$. Since $f$ is bounded below, it follows that

$$
\lim _{k \rightarrow \infty}\left(f\left(x_{k}\right)-f\left(x_{k+1}\right)\right)=0
$$

Now observe that $\Phi_{k}(\theta)$ is a convex function with the minimum value in point

$$
\theta_{m}=\frac{g_{k}^{T} g_{k}}{t_{k}\left(g_{k}^{T} \nabla^{2} f\left(x_{k}\right) g_{k}\right)}>0
$$

On the other hand, $\Phi_{k}(0)=f\left(x_{k}\right)$ and $\Phi_{k}\left(\theta_{u}\right)=f\left(x_{k}\right)$, where $\theta_{u}=2 \theta_{m}$. But,

$$
\Phi_{k}\left(\theta_{m}\right)=f\left(x_{k}\right)-\frac{\left(g_{k}^{T} g_{k}\right)^{2}}{2\left(g_{k}^{T} \nabla^{2} f\left(x_{k}\right) g_{k}\right)}<f\left(x_{k}\right)
$$

Therefore, for $\theta \in\left[0,2 \theta_{m}\right], \Phi_{k}(\theta) \leq \Phi_{k}(0)$.
There exists some $\beta \in\left(0, \theta_{m}\right)$ with $\beta<1$ such that $\beta \leq \bar{\theta} \leq 2 \theta_{m}-\beta$. Therefore, there exists a subsequence $\theta_{k_{j}}$ contained in the interval $\left[\beta, 2 \theta_{m}-\beta\right]$. Using again the convexity of function $\Phi_{k}(\theta)$ we get that

$$
\Phi_{k}(0)-\Phi_{k}\left(\beta \theta_{m}\right) \geq-\beta\left[\Phi_{k}\left(\theta_{m}\right)-\Phi_{k}(0)\right] .
$$

But,

$$
\Phi_{k}\left(\theta_{m}\right)-\Phi_{k}(0)=-\frac{\left(g_{k}^{T} g_{k}\right)^{2}}{2\left(g_{k}^{T} \nabla^{2} f\left(x_{k}\right) g_{k}\right)}
$$

Hence,

$$
\Phi_{k}(0)-\Phi_{k}\left(\beta \theta_{m}\right) \geq \frac{\beta}{2} \frac{\left(g_{k}^{T} g_{k}\right)^{2}}{\left(g_{k}^{T} \nabla^{2} f\left(x_{k}\right) g_{k}\right)} \geq \frac{\beta}{2 \lambda_{\max }}\left\|g_{k}\right\|_{2}^{2}
$$

Therefore

$$
f\left(x_{k_{j}}\right)-f\left(x_{k_{j}+1}\right) \geq \frac{\beta}{2 \lambda_{\max }}\left\|g_{k}\right\|_{2}^{2} .
$$

But, $f\left(x_{k_{j}}\right)-f\left(x_{k_{j}+1}\right) \rightarrow 0$ and as a consequence $g_{k_{j}}$ goes to zero, i.e. $x_{k j}$ converges to $x^{*}$. Having in view that $f\left(x_{k}\right)$ is an nonincreasing sequence, it follows that $f\left(x_{k}\right)$ converges to $f\left(x^{*}\right)$.

In the following let us assume that $f$ is strongly convex and the sublevel set $S=$ $\left\{x \in \operatorname{dom} f: f(x) \leq f\left(x_{0}\right)\right\}$ is closed. Strong convexity of $f$ on $S$ involves that there exists the constants $m$ and $M$ such that $m I \leq \nabla^{2} f(x) \leq M I$, for all $x \in S$. A consequence of strong convexity of $f$ on $S$ is that we can bound $f^{*}$ as:

$$
\begin{equation*}
f(x)-\frac{1}{2 m}\|\nabla f(x)\|_{2}^{2} \leq f^{*} \leq f(x)-\frac{1}{2 M}\|\nabla f(x)\|_{2}^{2} \tag{7}
\end{equation*}
$$

In these circumstances the following theorem can be proved.
Theorem 2. For strongly convex functions the Relaxed Gradient Descent algorithm with backtracking is linear convergent and

$$
\begin{equation*}
f\left(x_{k}\right)-f^{*} \leq\left(\prod_{i=0}^{k-1} c_{i}\right)\left(f\left(x_{0}\right)-f^{*}\right) \tag{8}
\end{equation*}
$$

where

$$
\begin{equation*}
c_{i}=1-\min \left\{2 m \alpha \theta_{i}, 2 m \alpha \theta_{i} s / M\right\}<1 \tag{9}
\end{equation*}
$$

Proof. Consider $0<\theta<1$, then

$$
f\left(x_{k}-\theta t_{k} g\right) \leq f\left(x_{k}\right)-\left(\theta-\frac{M t_{k}}{2} \theta^{2}\right) t_{k}\left\|g_{k}\right\|_{2}^{2}
$$

Notice that $\theta-\frac{M t_{k}}{2} \theta^{2}$ is a concave function and for all $0 \leq \theta \leq 1 / M t_{k}, \theta-\frac{M t_{k}}{2} \theta^{2} \geq \frac{\theta}{2}$. Hence

$$
f\left(x_{k}-\theta t_{k} g\right) \leq f\left(x_{k}\right)-\frac{\theta}{2} t_{k}\left\|g_{k}\right\|_{2}^{2} \leq f\left(x_{k}\right)-\alpha \theta t_{k}\left\|g_{k}\right\|_{2}^{2}
$$

since $\alpha \leq 1 / 2$. Therefore the backtracking line search procedure terminates either with $t_{k}=1$ or with a value $t_{k} \geq s / M$. With this, at step $k$ we can get a lower bound on the decrease of the function. In the first case we have

$$
f\left(x_{k+1}\right) \leq f\left(x_{k}\right)-\alpha \theta_{k}\left\|g_{k}\right\|_{2}^{2}
$$

and in the second one

$$
f\left(x_{k+1}\right) \leq f\left(x_{k}\right)-\alpha \theta_{k} \frac{s}{M}\left\|g_{k}\right\|_{2}^{2} .
$$

Therefore, we have

$$
f\left(x_{k+1}\right) \leq f\left(x_{k}\right)-\min \left\{\alpha \theta_{k}, \alpha \theta_{k} \frac{s}{M}\right\}\left\|g_{k}\right\|_{2}^{2}
$$

Hence

$$
f\left(x_{k+1}\right)-f^{*} \leq f\left(x_{k}\right)-f^{*}-\min \left\{\alpha \theta_{k}, \alpha \theta_{k} \frac{s}{M}\right\}\left\|g_{k}\right\|_{2}^{2} .
$$

But, from (7) it follows that $\left\|g_{k}\right\|_{2}^{2} \geq 2 m\left(f\left(x_{k}\right)-f^{*}\right)$. Therefore, combining this with the above relation we get

$$
f\left(x_{k+1}\right)-f^{*} \leq\left(1-\min \left\{2 m \alpha \theta_{k}, 2 m \alpha \theta_{k} \frac{s}{M}\right\}\right)\left(f\left(x_{k}\right)-f^{*}\right)
$$

Denoting $c_{k}=1-\min \left\{2 m \alpha \theta_{k}, 2 m \alpha \theta_{k} \frac{s}{M}\right\}$ it follows that for every $k=0,1, \ldots$

$$
f\left(x_{k+1}\right)-f^{*} \leq c_{k}\left(f\left(x_{k}\right)-f^{*}\right)
$$

which prove the second part of the theorem. Since $c_{k}<1$, the sequence $f\left(x_{k}\right)$ converges to $f^{*}$ like a geometric series with an exponent that partialy depends on the condition number bound $M / m$, the backtracking parameters $\alpha$ and $s$, the sequence $\theta_{k}$ of random uniform distributed numbers in $(0,1)$ interval and on the initial suboptimality. Therefore the RGD algorithm is linear convergent.

For strongly convex functions the behavior of the gradient descent algorithm is given by:

$$
\begin{equation*}
f\left(x_{k}\right)-f^{*} \leq c^{k}\left(f\left(x_{0}\right)-f^{*}\right) \tag{10}
\end{equation*}
$$

where

$$
\begin{equation*}
c=1-\min \left\{2 m \alpha, 2 m \alpha \frac{s}{M}\right\}<1 \tag{11}
\end{equation*}
$$

Observe that for every $k=0,1, \ldots$, since $\theta_{k}<1$, it follows that $c_{k}>c$.

## 3. A New Algorithm for Unconstrained Optimization

As we mentioned in introduction, for problem (1) Barzilai and Borwein [2] suggested an algorithm which essentially is a gradient one, where the choice of the stepsize along the negative gradient is derived from a two-point approximation to the secant equation from quasi-Newton methods. Considering $D_{k}=\gamma_{k} I$ as an approximation to the Hessian of $f$ at $x_{k}$, they chose $\gamma_{k}$ such that

$$
D_{k}=\arg \min \left\|D s_{k}-y_{k}\right\|_{2}
$$

where $s_{k}=x_{k}-x_{k-1}$ and $y_{k}=\nabla f\left(x_{k}\right)-\nabla f\left(x_{k-1}\right)$, yielding

$$
\begin{equation*}
\gamma_{k}^{B B}=\frac{s_{k}^{T} y_{k}}{s_{k}^{T} s_{k}} \tag{12}
\end{equation*}
$$

With these, the method of Barzilai and Borwein is given by the following iterative scheme:

$$
\begin{equation*}
x_{k+1}=x_{k}-\frac{1}{\gamma_{k}^{B B}} \nabla f\left(x_{k}\right) . \tag{13}
\end{equation*}
$$

Mainly, the sequence $\left\{x_{k}\right\}$ generated by the BB method uses two initial vectors $x_{0}$ and $x_{1}$. Having in view its simplicity and numerical efficiency for well-conditioned problems, proved inter alia by Raydan [29] and Fletcher [9], the Barzilai and Borwein gradient method has received a great deal of attention. However, like all steepest descent and conjugate gradient methods, the BB method becomes slow when the problems happens to be more ill-conditioned [12].

In the following I suggest another procedure for computing an approximation of the Hessian of the function $f$ at $x_{k}$ which can be considered to get the stepsize along the negative gradient. Let us consider the initial point $x_{0}$ where $f\left(x_{0}\right)$ and $g_{0}=\nabla f\left(x_{0}\right)$ can immediately be computed. Using the backtracking procedure (initialized with $t=1$ ) we can compute the steplength $t_{0}$ with which the next estimate $x_{1}=x_{0}-t_{0} g_{0}$ is computed, where again we can compute $f\left(x_{1}\right)$ and $g_{1}=\nabla f\left(x_{1}\right)$. So, the first step is computed using the backtracking along the negative gradient. Now, in point $x_{k+1}=x_{k}-t_{k} g_{k}, k=0,1, \ldots$ we have:

$$
\begin{equation*}
f\left(x_{k+1}\right)=f\left(x_{k}\right)-t_{k} g_{k}^{T} g_{k}+\frac{1}{2} t_{k}^{2} g_{k}^{T} \nabla^{2} f(z) g_{k} \tag{14}
\end{equation*}
$$

where $z \in\left[x_{k}, x_{k+1}\right]$. Having in view the local character of the searching procedure and that the distance between $x_{k}$ and $x_{k+1}$ is enough small we can choose $z=x_{k+1}$ and consider $\gamma\left(x_{k+1}\right) I$ as an approximation of the $\nabla^{2} f\left(x_{k+1}\right)$, where $\gamma\left(x_{k+1}\right) \in R$. This is an anticipative point of view, in which the approximation of the Hessian in point $x_{k+1}$ is computed using the local information from point $x_{k}$. Therefore we can write:

$$
\begin{equation*}
\gamma\left(x_{k+1}\right)=\frac{2}{g_{k}^{T} g_{k}} \frac{1}{t_{k}^{2}}\left[f\left(x_{k+1}\right)-f\left(x_{k}\right)+t_{k} g_{k}^{T} g_{k}\right] \tag{15}
\end{equation*}
$$

Now, in order to compute the next estimation $x_{k+2}=x_{k+1}-t_{k+1} g_{k+1}$ we must consider a procedure to determine the stepsize $t_{k+1}$. For this let us consider the function:

$$
\Phi_{k+1}(t)=f\left(x_{k+1}\right)-t g_{k+1}^{T} g_{k+1}+\frac{1}{2} t^{2} \gamma\left(x_{k+1}\right) g_{k+1}^{T} g_{k+1}
$$

Observe that $\Phi_{k+1}(0)=f\left(x_{k+1}\right)$ and $\Phi_{k+1}^{\prime}(0)=-g_{k+1}^{T} g_{k+1}<0$. Therefore $\Phi_{k+1}(t)$ is a convex function for all $t \geq 0$. To have a minimum for $\Phi_{k+1}(t)$ we must have $\gamma\left(x_{k+1}\right)>$ 0 . Considering for the moment that $\gamma\left(x_{k+1}\right)>0$, then from $\Phi_{k+1}^{\prime}(t)=0$ we get

$$
\begin{equation*}
\bar{t}_{k+1}=\frac{1}{\gamma\left(x_{k+1}\right)}, \tag{16}
\end{equation*}
$$

as the minimum of $\Phi_{k+1}(t)$. Now,

$$
\Phi_{k+1}\left(\bar{t}_{k+1}\right)=f\left(x_{k+1}\right)-\frac{1}{2 \gamma\left(x_{k+1}\right)}\left\|g_{k+1}\right\|_{2}^{2}
$$

which shows that if $\gamma\left(x_{k+1}\right)>0$, then the value of function $f$ is reduced. This suggests us to determine the stepsize $t_{k+1}$ as:

$$
\begin{equation*}
t_{k+1}=\underset{t \leq \bar{t}_{k+1}}{\arg \min } f\left(x_{k+1}-t g_{k+1}\right) \tag{17}
\end{equation*}
$$

using the backtracking procedure.
To complete the algorithm we must consider the situation when $\gamma\left(x_{k+1}\right)<0$. If $f\left(x_{k+1}\right)-$ $f\left(x_{k}\right)+t_{k} g_{k}^{T} g_{k}<0$, then the reduction $f\left(x_{k}\right)-f\left(x_{k+1}\right)$ is greater that $t_{k} g_{k}^{T} g_{k}$. In this case we change a little the stepsize $t_{k}$ as $t_{k}+\eta_{k}$ in such a manner that

$$
f\left(x_{k+1}\right)-f\left(x_{k}\right)+\left(t_{k}+\eta_{k}\right) g_{k}^{T} g_{k}>0 .
$$

To get a value for $\eta_{k}$ let us select a $\delta>0$, enough small, and consider:

$$
\begin{equation*}
\eta_{k}=\frac{1}{g_{k}^{T} g_{k}}\left[f\left(x_{k}\right)-f\left(x_{k+1}\right)-t_{k} g_{k}^{T} g_{k}\right]+\delta \tag{18}
\end{equation*}
$$

with which a new value for $\gamma\left(x_{k+1}\right)$ can be computed as:

$$
\begin{equation*}
\gamma\left(x_{k+1}\right)=\frac{2}{g_{k}^{T} g_{k}} \frac{1}{\left(t_{k}+\eta_{k}\right)^{2}}\left[f\left(x_{k+1}\right)-f\left(x_{k}\right)+\left(t_{k}+\eta_{k}\right) g_{k}^{T} g_{k}\right] \tag{19}
\end{equation*}
$$

The corresponding New gradient descent Algorithm (NA) is as follows:

## The New Algorithm (NA)

Step 1. Select $x_{0} \in \operatorname{dom} f$ and compute $f\left(x_{0}\right), g_{0}=\nabla f\left(x_{0}\right)$ and $t_{0}=\underset{t<1}{\arg \min } f\left(x_{0}-\right.$ $\left.t g_{0}\right)$. Compute $x_{1}=x_{0}-t_{0} g_{0}, f\left(x_{1}\right)$ and $g_{1}=\nabla f\left(x_{1}\right)$. Set $k=0$.

Step 2. Test for continuation. If some criteria for stopping the algorithm are satisfied, then stop; otherwise continue with step 3.

Step3. Compute the (scalar) approximation, $\gamma\left(x_{k+1}\right)$, of the Hessian of function $f$ at $x_{k+1}$ as in (15).

Step 4. If $\gamma\left(x_{k+1}\right)<0$, then select $\delta>0$ and compute a new value for $\gamma\left(x_{k+1}\right)$ as in (19), where $\eta_{k}$ is given by (18).

Step 5. Compute the initial stepsize

$$
\bar{t}_{k+1}=\frac{1}{\gamma\left(x_{k+1}\right)},
$$

with which a backtracking procedure is performed in the next step.
Step 6. Using a backtracking procedure, determine the step length $t_{k+1}$ as:

$$
t_{k+1}=\underset{t \leq \bar{t}_{k+1}}{\arg \min } f\left(x_{k+1}-t g_{k+1}\right) .
$$

Step 7. Update the variables: $x_{k+2}=x_{k+1}-t_{k+1} g_{k+1}$, set $k=k+1$ and go to step 2.

Example 1. (continued) For example 1 the number of iterations and the steplength corresponding to the Barzilai-Borwein algorithm and the New Algorithm are given in table 1 b .

Table 1b. Number of iterations and the step length of BB and NA.

|  | Barzilai-Borwein (BB) |  | New Algorithm (NA) |  |  |
| :---: | :---: | :---: | :---: | :---: | :---: |
| $\mathbf{n}$ | \# iter | average step | \# iter | average step | $\boldsymbol{\gamma}<\mathbf{0}$ |
| 500 | 748 | 0.008818 | 706 | 0.009316 | 0 |
| 1000 | 1353 | 0.004934 | 1269 | 0.004967 | 0 |
| 2000 | 2675 | 0.002398 | 2410 | 0.002510 | 0 |
| 3000 | 3526 | 0.001740 | 3282 | 0.001687 | 0 |
| 4000 | 4194 | 0.001319 | 4895 | 0.001289 | 0 |
| 5000 | 6227 | 0.001031 | 6113 | 0.001020 | 0 |

where the elements in column below $\gamma<0$ represents the number of iterations in which $\gamma\left(x_{k+1}\right)<0$. Observe that the behaviour of the New Algorithm is very close to that of Barzilai-Borwein. In fact, the difference $\gamma\left(x_{k+1}\right)-\gamma_{k}^{B B}$ is very small, as it is illustrated in figure 2.

Figure 2: Difference $\gamma\left(x_{k+1}\right)-\gamma_{k}^{B B}$.

However, this is not the typical behaviour of the NA algorithm. Generally, for the most numerical experiments we notice that $\gamma\left(x_{k+1}\right) \geq \gamma_{k}^{B B}$.

The analysis of convergence of this algorithm is given by the following theorems.
Theorem 3. For strongly convex functions the New Algorithm with backtracking is linear convergent and

$$
f\left(x_{k}\right)-f^{*} \leq\left(\prod_{i=0}^{k-1} c_{i}\right)\left(f\left(x_{0}\right)-f^{*}\right)
$$

where

$$
c_{i}=1-\min \left\{2 m \alpha, 2 m \alpha s^{p_{i}}\right\}<1
$$

and $p_{i} \geq 1$ is an integer, $\left(p_{i}=1,2, \ldots\right.$ given by the backtracking procedure).
Proof. This is very similar with the proof in theorem 2 above. We can write:

$$
f\left(x_{k+1}\right)=f\left(x_{k}\right)-\left(t-\frac{1}{2} t^{2} \gamma\left(x_{k+1}\right)\right)\left\|g_{k}\right\|_{2}^{2}
$$

But, $t-t^{2} \gamma\left(x_{k+1}\right) / 2$ is a concave function, and for all $0 \leq t \leq 1 / \gamma\left(x_{k+1}\right), t-t^{2} \gamma\left(x_{k+1}\right) / 2 \geq$ $t / 2$. Hence

$$
f\left(x_{k+1}\right) \leq f\left(x_{k}\right)-\frac{t}{2}\left\|g_{k}\right\|_{2}^{2} \leq f\left(x_{k}\right)-\alpha t\left\|g_{k}\right\|_{2}^{2} .
$$

The backtracking procedure terminates either with $t=1$ or with $t=s^{p_{k}}$, where $p_{k}$ is an integer. Therefore

$$
f\left(x_{k+1}\right) \leq f\left(x_{k}\right)-\min \left\{\alpha, \alpha s^{p_{k}}\right\}\left\|g_{k}\right\|_{2}^{2} .
$$

Having in view that for strongly convex functions $\left\|g_{k}\right\|_{2}^{2} \geq 2 m\left(f\left(x_{k}\right)-f^{*}\right)$ it follows that

$$
f\left(x_{k+1}\right)-f^{*} \leq c_{k}\left(f\left(x_{k}\right)-f^{*}\right)
$$

where $c_{k}=1-\min \left\{2 m \alpha, 2 m \alpha s^{p_{k}}\right\}$. Since $c_{k}<1$ the sequence $f\left(x_{k}\right)$ is linear convergent, like a geometric series, to $f^{*}$.

Theorem 4. For every $k=0,1, \ldots \gamma\left(x_{k+1}\right)$, generated by the New Algorithm, is bounded away form zero.

Proof. For every $k=0,1, \ldots$ we know that $f\left(x_{k+1}\right)-f\left(x_{k}\right)+t_{k} g_{k}^{T} g_{k}>0$. Therefore, $f\left(x_{k}\right)-f\left(x_{k+1}\right)<t_{k} g_{k}^{T} g_{k}$. With this we have:

$$
\gamma\left(x_{k+1}\right)=\frac{2}{t_{k}}-\frac{2\left(f\left(x_{k}\right)-f\left(x_{k+1}\right)\right)}{t_{k}^{2}\left(g_{k}^{T} g_{k}\right)}>\frac{2}{t_{k}}-\frac{2 t_{k}\left(g_{k}^{T} g_{k}\right)}{t_{k}^{2}\left(g_{k}^{T} g_{k}\right)}=0
$$

Therefore the step 5 of the NA is well defined. However, towards the final iterations of the algorithm, especially when the accuracy requirements are too high, it is possible that $\left(f\left(x_{k+1}\right)+t_{k} g_{k}^{T} g_{k}\right)-f\left(x_{k}\right)<0$, but very close to zero. This is because $g_{k}^{T} g_{k}$ is too small. That means the reduction in function values is too small. The remedy we have considered in this situation is to increase a little the steplength in order to compensate the accuracy requirements.

## 4. Numerical Experiments

In this section we report some numerical results obtained by a FORTRAN implemention of the above gradient descent algorithms for 11 functions. In all experiments the backtracking procedure considers $\alpha=0.0001$ and $s=0.8$. The criteria for stopping the algorithms are those used in example 1 above. For each function the initial point has been presented. Each table presents the number of iterations as well as the average stepsize corresponding to algorithms. Tables *a present the number of iterations and the average steplength for the

GD and the RGD algorithms. Tables *b give the number of iterations, corresponding to the BB and the NA algorithms. Tables *c show the number of iterations of an implementation of BB algorithm. Tables *d present the number of iterations of NA for different values of $\delta$. The number of iterations in which $\gamma\left(x_{k+1}\right)<0$ or $\gamma^{B B}<0$ is shown in column below $\gamma$.

Example 2. $f(x)=\sum_{i=1}^{n} \frac{i}{10}\left(\exp \left(x_{i}\right)-x_{i}\right), x_{0}=[1,1, \ldots, 1]$.

Table 2a. Number of iterations and the average steplength of GD and RGD.

Some comments are in order.

Both algorithms are linear convergent. Modifying only the steplength along the negative gradient we get linear convergent algorithms, i.e. the error $f\left(x_{k}\right)-f^{*}$ converges to zero approximately as a geometric series.

The convergence rate depends greatly on the condition number of the Hessian of the minimizing function. For well conditioned convex functions both algorithms are improvements of the classical gradient descent algorithm. For ill-conditioned functions these algorithms, like any gradient descent one, are so slow that they have no value in practice.

Generally, $\gamma\left(x_{k+1}\right) \geq \gamma_{k}^{B B}$ showing that the initial step in backtracking procedure of NA is lower than the corresponding initial step of Barzilai-Borwein approach. However, along the iterations $\gamma\left(x_{k+1}\right)$ is very close to $\gamma_{k}^{B B}$. This give us the motivation to modify the Barzilai-Borwein algorithm when $\gamma_{k}^{B B}<0$. If $\gamma_{k}^{B B}<0$, as in exemples 3 and 10 above, then we can consider in the Barzilai-Borwein algorithm $\gamma\left(x_{k+1}\right)$ instead of $\gamma_{k}^{B B}$.

Refering to the number of iterations corresponding to GD, RGD, BB and NA algorithms, from the above tables the following cumulative results have been obtained.

Table 13. Number of iterations. Cumulative results for tables *a and *b.

## 5. Conclusion

The main contributions of this paper are as following. Firstly, it extends the relaxation idea considered by Raydan and Svaiter [30] for the quadratic positive definite functions to the nonlinear convex optimization. It is shown that a simple modification of the steplength by means of a random variable uniformly distributed in $(0,1)$, for the strongly convex functions, represents an improvement of the classical gradient descent algorithm. Secondly, a new gradient descent algorithm is proposed in which the step length is computed by backtracking using a simple approximation of the Hessian. This new approach compares favourable with Barzilai-Borweins, for well conditioned convex functions this being an improvement of the classical gradient descent algorithm. The general conclusion is that using only the local information given by the gradient of the minimizing function, any procedure for step length computation, does not change the linear convergence property of the gradient descent algorithms.
